Computer Science 1000: Part #7

Programming in Python

Programming Languages: An Overview
The Python Programming Language
Implementing Programming
Programming Languages: An Overview

- Disadvantages of assembly language:
  1. Low-level / concrete conception of data, e.g., numbers, registers $\leftrightarrow$ memory.
  2. Low-level / concrete conception of task, e.g., ADD, COMPARE, JUMP.
  4. Not like natural language.

- Advantages of high-level programming language:
  1. High-level / abstract conception of data, e.g., lists, data item $\leftrightarrow$ data item.
  2. High-level / abstract conception of task, e.g., IF-THEN-ELSE, WHILE loop.
  4. Like natural language.
A programming language is defined by the valid statements in that language (syntax) and what those statements do (semantics).

A programming language can be compiled (whole program translated into machine language) or interpreted (individual program-statements translated as needed).

Machine-independence achieved formally by standards, e.g., ANSI, IEEE, and implemented in practice by intermediate languages, e.g., bytecode.

Machine-independence is often violated, e.g., may exploit particular machines and/or modify language features; additional incompatible variants may arise as language evolves over time, e.g., Python 2.x vs. Python 3.x.
Figure 8.1
Transitions of a High-level Language Program
Two reasons why there are many programming languages:

1. Languages are designed for different tasks, e.g.,
   - Scientific computation (FORTRAN)
   - Business applications (COBOL)
   - Web-page creation (HTML)
   - Database creation (SQL)

2. Languages are designed for different ways of thinking about programming, e.g.,
   - Procedural programming (FORTRAN, COBOL, C)
   - Object-oriented programming (OOP) (C++, Java)
   - Logic Programming (Prolog)
   - Script-based programming (Javascript, Ruby)
The Python Programming Language: Overview

- Created by Guido van Rossum in 1991 as an easy-to-learn general-purpose programming language.
- Procedural scripting language that allows but does not require OOP (“as OOP as you wanna be”).
- Key design principles:
  - Control structure indicated by indentation.
  - Powerful built-in data types.
  - Any variable can refer to any type of data, and this type can change as a program executes.
- Primarily interpreted but can be compiled for speed.
- General machine-independence achieved by bytecode; however, Python 3.x not directly backward-compatible with Python 2.x.
The Python Programming Language: A First Example Program

1. # Example program; adapted from
2. # Online Python Supplement, Figure 1.2
3.
4. speed = input("Enter speed (mph): ")
5. speed = int(speed)
6. distance = input("Enter distance (miles): ")
7. distance = float(distance)
8.
9. time = distance / speed
10,
11. print("At", speed, "mph, it will take")
12. print(time, "hours to travel", \
13.      distance, "miles.")
The Python Programming Language: A First Example Program (Cont’d)

- Python programs are stored in files with extension `.py`, e.g., `example1.py`.

- When this program is executed using a Python interpreter and the user enters the boldfaced values, this is printed:

  ```plaintext
  Enter speed (mph): 58
  Enter distance (miles): 657.5
  At 58 mph it will take 11.3362068966 hours to travel 657.5 miles.
  ```
The Python Programming Language: A First Example Program (Cont’d)

- Line numbers not necessary; are given here to allow easy reference to program lines.
- Lines beginning with hash (#) are comments (Lines 1-2); a prologue comment at the top of the program gives a program’s purpose and creation / modification history.
- Comment and blank lines (Lines 3, 8, and 10) are ignored.
- Each line is a program statement; multiline statements are linked by end-of-line backslashes (\) (Lines 12-13).
- No variable-type declaration statements; this is handled by assignment statements (Lines 4-7 and 9).
- This program also has basic I/O statements (Lines 4, 6, and 11-13); control statements will be shown later.
The Python Programming Language: Assignment Statements

• General form: \textit{variable} = \textit{expression}, e.g.,

  \begin{itemize}
  \item \texttt{index} = 1
  \item \texttt{myDistanceRate} = \texttt{curDistanceRate} * 1.75
  \item \texttt{name} = "Todd Wareham"
  \item \texttt{curDataFilename} = \texttt{main} + "\.txt"
  \item \texttt{callList} = ["Bob", "Sue", "Anne"]
  \end{itemize}

• Sets the value of \textit{variable} to the value of \textit{expression}.

  \begin{itemize}
  \item If \textit{variable} did not already exist, it is created.
  \item If \textit{variable} did already exist, its previous value is replaced. Note that the data-type of this previous value need not be that of the value created by \textit{expression}.
The Python Programming Language: Assignment Statements (Cont’d)

- Variable names (also called *identifiers*) can be arbitrary sequences of letters, numbers and underscore symbols (_) such that (1) the first symbol is a letter and (2) the sequence is not already used in the Python language, e.g., *if*, *while*.

- Python is case-sensitive wrt letter capitalization, e.g., *myList* is a different variable than *mylist*.

- By convention, variables are a mix of lower- and uppercase letters and numbers; words may be combined to form a variable name in so-called “camel-style”, e.g., *myList*, *dataFilename1*. 
By convention, constants use only upper-case letters and numbers, e.g., \( \pi \), TYPE1COLOR.

Though constants should not change value, they are still technically variables, e.g.,

\[
\begin{align*}
\ldots \\
\pi &= 3.1415927 \\
\ldots \\
\pi &= -1 \\
\ldots
\end{align*}
\]

It is up to programmers to make sure that such changes do not happen.

Underscores reserved for Python system constants.
The Python Programming Language: Assignment Statements (Cont’d)

- The `int` and `float` data-types
  
  - Encode “arbitrary” integers, e.g., -1001, 0, 57, and floating-point numbers, e.g. -100.2, 3.1415927.
  
  - Support basic arithmetic operations (+, -, *, /); also have floor-division (//) and remainder (%) operations, e.g.,

  \[
  \begin{align*}
  7 \div 2 & \implies 3.5 \\
  7 \div\!\div 2 & \implies 3 \\
  7 \mod 2 & \implies 1
  \end{align*}
  \]
  
  Behaviour of `/` incompatible with Python 2.x.

- Many additional math functions and constants available in the `math` module, e.g., `abs(x)`, `pow(base, exponent)`, `sqrt(x)`, `pi`. 
The Python Programming Language:
Assignment Statements (Cont’d)

radius = input("Enter radius: ")
radius = float(radius)
area = 3.1415927 * radius * radius
print("Circle Area = ", area)

import math

radius = input("Enter radius: ")
radius = float(radius)
area = math.pi * math.pow(radius, 2)
print("Circle Area = ", area)
The Python Programming Language: Assignment Statements (Cont’d)

- The `str` data-type
  - Encodes “arbitrary” character strings, e.g., "657.5", "Todd Wareham".
  - Supports many operations, e.g.,
    - Concatenation (+) ("Todd" + " " + "Wareham" \(\rightarrow\) "Todd Wareham")
    - Lower-casing ("Todd".lower() \(\rightarrow\) "todd")
    - Upper-casing ("Todd".upper() \(\rightarrow\) "TOODD")
  - Convert between data types using **type casting** functions, e.g., float("657.5") \(\rightarrow\) 657.5, int(657.5) \(\rightarrow\) 657, str(58) \(\rightarrow\) "58".
The Python Programming Language: Assignment Statements (Cont’d)

- The list data-type
  - Encodes “arbitrary” lists, e.g., [22, 5, 13, 57, -1], ["Bob", "Sue", "Anne"].
  - Items in list L indexed from 0 as L[IND], e.g., if L = [22, 5, 13, 57, -1], L[0] ⇒ 22 and L[4] ⇒ -1.
  - Supports many operations, e.g.,
    - Number of values in list (len(L))
    - Append x to right end of list (L.append(x))
    - List sorting (L.sort())
    - Get list maximum value (max(L))
The Python Programming Language: I/O Statements

- Keyboard input done via `input(string)`.
  - Prints `string` on screen, waits for user to enter input followed by a key return, and then returns this input-string.
  - Input-string can be converted as necessary by type-casting functions, e.g., `float(radius)`.

- Screen output done via `print(plist)`.
  - Comma-separated items in `plist` converted to strings as necessary and concatenated, and resulting string printed.
  - By default, each `print`-statement prints one line; can override this by making `end = " "`) the last item.
  - Can include escape characters to modify printout, e.g., `\t (tab), \n (newline),`

- Above I/O incompatible with Python 2.x.
The statements

```python
print("Here is \t a weird")
print("way \n of printing ", end = " ")
print("this message.")
```

print out

Here is a weird way of printing this message.
The Python Programming Language: A First Example Program Redux

1. # Example program; adapted from
2. # Online Python Supplement, Figure 1.2
3. 
4. speed = input("Enter speed (mph): ")
5. speed = int(speed)
6. distance = input("Enter distance (miles): ")
7. distance = float(distance)
8. 
9. time = distance / speed
10.
11. print("At", speed, "mph, it will take")
12. print(time, "hours to travel", \
13.     distance, "miles.")
The Python Programming Language: Control Statements

- Sequential Statements (**Statement Block**):
  - A set of statements with the same indentation.
  - All Python programs seen so far are purely sequential.

- Conditional Statements:
  - General form:
    ```python
    if (CONDITION1):
      ⟨CONDITION1 Block⟩
    elif (CONDITION2):
      ⟨CONDITION2 Block⟩
    ... 
    else:
      ⟨ELSE Block⟩
    ```
  - *elif* and *else* blocks are optional.
Conditions typically based on variable-comparisons, possibly connected together by logical operators.

<table>
<thead>
<tr>
<th>Expression</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>x == y</td>
<td>x equal to y</td>
</tr>
<tr>
<td>x != y</td>
<td>x not equal to y</td>
</tr>
<tr>
<td>x &lt; y</td>
<td>x less than y</td>
</tr>
<tr>
<td>x &lt;= y</td>
<td>x less than or equal to y</td>
</tr>
<tr>
<td>x &gt; y</td>
<td>x greater than y</td>
</tr>
<tr>
<td>x &gt;= y</td>
<td>x greater than or equal to y</td>
</tr>
<tr>
<td>E1 and E2</td>
<td>logical AND of E1 and E2</td>
</tr>
<tr>
<td>E1 or E2</td>
<td>logical OR of E1 and E2</td>
</tr>
<tr>
<td>not E1</td>
<td>logical NOT of E1</td>
</tr>
</tbody>
</table>
The Python Programming Language: Control Statements (Cont’d)

```python
if ((number % 2) == 0):
    print("number is even")

if ((number >= 1) and (number <= 10)):
    print("number in range")

if (1 <= number <= 10):
    print("number in range")

if not (1 <= number <= 10):
    print("number not in range")
```
if ((number % 2) == 0):
    print("number is even")
else:
    print("number is odd")

if (number < 10):
    print("number less than 10")
elif (number == 10):
    print("number equal to 10")
else:
    print("number greater than 10")
The Python Programming Language: Control Statements (Cont’d)

- Conditional Looping Statement:
  - General form:
    ```python
    while (CONDITION):
        ⟨ Loop Block ⟩
    ```
  - Executes **Loop Block** as long as **CONDITION** is True.

- Iterated Looping Statement:
  - General form:
    ```python
    for (x in LIST):
        ⟨ Loop Block ⟩
    ```
  - Executes **Loop Block** for each item \( x \) in **LIST**.
Print the numbers between 1 and 100 inclusive:

number = 1
while (number <= 100):
    print number
    number = number + 1

for (number in range(1, 101)):
    print number
Sum the numbers in a −1-terminated list:

```python
sum = 0
number = int(input("Enter number: "))
while (number != -1):
    sum = num + number
    number = int(input("Enter number: "))
print("Sum is ", sum)
```
Find the maximum value in a -1-terminated list:

```python
maxValue = -99
number = int(input("Enter number: "))
while (number != -1):
    if (number > maxValue):
        maxValue = number
    number = int(input("Enter number: "))
print("Maximum value is ", maxValue)
```
Store the values in a −1-terminated list in $L$:

```python
L = []
number = int(input("Enter number: "))
while (number != -1):
    L.append(number)

Print the values in list $L$ (one per line):

```python
for (number in L):
    print(number)
```
Sort the \( n \) values in list \( L \) (Selection Sort pseudocode):

\[
\text{ENDUNSORT} = n \\
\text{While (ENDUNSORT} > 1) \text{ do} \\
\quad \text{FPOS} = 1 \\
\quad \text{for IND} = 2 \text{ to ENDUNSORT do} \\
\quad \quad \text{If } L_{\text{IND}} > L_{\text{FPOS}} \text{ then} \\
\quad \quad \quad \text{FPOS} = \text{IND} \\
\quad \text{TMP} = L_{\text{ENDUNSORT}} \\
\quad L_{\text{ENDUNSORT}} = L_{\text{FPOS}} \\
\quad L_{\text{FPOS}} = \text{TMP} \\
\text{ENDUNSORT} = \text{ENDUNSORT} - 1
\]
Sort the values in list $L$ (Selection Sort):

```python
endUnSort = len(L) - 1
while (endUnSort > 0):
    maxPos = 0
    for ind in range(1, endUnSort + 1):
        if (L[ind] > L[maxPos]):
            maxPos = ind
    tmp = L[endUnSort]
    L[endUnSort] = L[maxPos]
    L[maxPos] = tmp
    endUnSort = endUnSort - 1
```
Store unique values in sorted list \( L \) in list \( L_{\text{Unique}} \):

\[
\begin{align*}
L_{\text{Unique}} &= [] \\
\text{curValue} &= L[0] \\
\text{for ind in range}(1, \text{len}(L)):\ \\
&\quad \text{if } (L[\text{ind}] \neq \text{curValue}): \\
&\quad \quad L_{\text{Unique}}.\text{append}(\text{curValue}) \\
&\quad \quad \text{curValue} = L[\text{ind}] \\
L_{\text{Unique}}.\text{append}(\text{curValue})
\end{align*}
\]
The Python Programming Language: Functions

- Compartamentalize data and tasks in programs with **functions**; allow implementation of divide-and-conquer-style programming.

- General form:

  ```python
  def funcName():
      ⟨ Function Block ⟩
  
def funcName(parameterList):
      ⟨ Function Block ⟩
  
def funcName(parameterList):
      ⟨ Function Block ⟩
      return value
  ```
The Python Programming Language:
Functions (Cont’d)

• A variable defined inside a function is a **local variable**; otherwise, it is a **global variable**.

• If a local variable has the same name as a global variable, the local variable is used inside the function.

• What does this print?

```python
def myFunc1():
    one = -1
    print one, two

one = 1
two = 2
myFunc1()
```
• The parameters in a function’s parameter-list match up with and get their values from the arguments in the argument-list of a function call in numerical order, not by parameter / argument name.

• What does this print?

```python
def myFunc2(one, two, three):
    print one, two, three

one = 1
two = 2
three = 3
myFunc2(two, three, one)
```
The value returned by a function can be captured by an assignment statement which has that function as the expression.

What does this print?

```python
def myFunc3(one, two, three):
    sum = (one + two) - three
    return sum

one = 1
two = 2
three = 3
result = myFunc3(two, three, one)
print result
```
• Eliminate global variables with **main functions**.

• What does this print?

```python
def myFunc4(one, two, three):
    sum = (one + two) - three
    return sum

def main():
    one = 1
    two = 2
    three = 3
    result = myFunc4(two, three, one)
    print(result)
```
The Python Programming Language: Functions (Cont’d)

- Compartmentalize data and tasks in programs with functions; allow implementation of **divide-and-conquer-style programming** (which is based on the levels-of-abstraction organizational principle).

- Functions useful in all stages of software development:
  1. Planning (View complex problem as set of simple subtasks)
  2. Coding (Code individual subtasks independently)
  3. Testing (Test individual subtasks independently)
  4. Modifying (Restrict changes to individual subtasks)
  5. Reading (Understand complex problem as set of simple subtasks)
Reading in and printing a \(-1\)-terminated list (Version #1):

\[
L = []
\]
\[
\text{number} = \text{int}(\text{input}("\text{Enter number: } "))
\]
\[
\text{while (number} \neq -1):
    \hspace{1em} L.\text{append}(\text{number})
\]
\[
\text{for (number} \text{in L}):
    \hspace{1em} \text{print}(\text{number})
\]
The Python Programming Language: Functions (Cont’d)

Reading in and printing a −1-terminated list (Version #2):

```python
def readList():
    L = []
    number = int(input("Enter number: "))
    while (number != -1):
        L.append(number)

def printList():
    for (number in L):
        print(number)

readList()
printList()
```
The Python Programming Language: Functions (Cont’d)

Reading in and printing a \(-1\)-terminated list (Version #3):

```python
def readList():
    number = int(input("Enter number: "))
    while (number != -1):
        L.append(number)

def printList():
    for (number in L):
        print(number)

L = []
readList()
paintList()
```
The Python Programming Language: Functions (Cont’d)

Reading in and printing a −1-terminated list (Version #4):

```python
def readList():
    L = []
    number = int(input("Enter number: "))
    while (number != -1):
        L.append(number)
    return L

def printList(L):
    for (number in L):
        print(number)

L = readList()
printList(L)
```
def readList():
    L = []
    number = int(input("Enter number: "))
    while (number != -1):
        L.append(number)
    return L

def printList(L):
    for (number in L):
        print(number)

def main():
    L = readList()
    printList(L)
The Python Programming Language: Functions (Cont’d)

Sort the values in list $L$ (Selection Sort) (Function):

```python
def sortList(L):
    endUnSort = len(L) - 1
    while (endUnSort > 0):
        maxPos = 0
        for ind in range(1, endUnSort + 1):
            if (L[ind] > L[maxPos]):
                maxPos = ind
        tmp = L[endUnSort]
        L[endUnSort] = L[maxPos]
        L[maxPos] = tmp
        endUnSort = endUnSort - 1
    return L
```
The Python Programming Language: Functions (Cont’d)

Compute unique values in sorted list \( L \) (Function):

```python
def getUniqueList(L):
    LUnique = []
    curValue = L[0]
    for ind in range(1, len(L)):
        if (L[ind] != curValue):
            LUnique.append(curValue)
            curValue = L[ind]
    LUnique.append(curValue)
    return LUnique
```
Main function for unique-value list program:

```python
def main():
    L = readList()
    L = sortList(L)
    L = getUniqueList(L)
    printList(L)
```
Implementing Programming: The Software Crisis

- Act of programming made easier by compilers, languages, and operating systems; problem of developing algorithms remained.
- Special notations like flowcharts help with small- and medium-size programs; hope was that appropriate management would help with large ones.
Implementing Programming: The Software Crisis (Cont’d)

The SABRE Airline Reservation System (1964)
Implementing Programming:
The Software Crisis (Cont’d)

IBM System/360 (1967)
Fred Brooks Jr. (1931–)

- OS/360 initially planned for 1965 costing $125M; limped to market in 1967 costing $500M, and virtually destroyed IBM’s in-house programming division.
- Brooks discussed causes in *The Mythical Man Month*.
As both larger programs and larger teams have more complex internal relationships, adding more programmers to larger projects makes things worse.
Software Engineering born at 1968 NATO-sponsored conference; goal of SE is to develop efficient processes for creating and maintaining correct software systems.

Many types of processes proposed, e.g., design and management methodologies (Agile), automatic software derivation methods; however, “No Silver Bullet” (Brooks).
